TABLE OF CONTENTS

ACKNOWLEDGEMENTS

INTRODUCTION

The impetus for this study of the postcranial skeletal characteristics of cattle, *Bos taurus*, and bison, *Bison bison*, was the examination by the Zooarchaeological Identification Centre, Canadian Museum of Nature, of several thousand well-preserved bones from a late 19th century archaeological site in the Cypress Hills of southwestern Saskatchewan. The zooarchaeological material recovered from Fort Walsh, a Northwest Mounted Police post, included all parts of the bovid skeleton, and accurate identification of the material was necessary for conclusions regarding the food supply of the men occupying the fort. During the 1870's the earliest cattle ranches were opening up in western Canada as the last of the large bison herds were hunted, and both the wild and domestic bovids were regular table fare. Since the bones of the two species are so similar, identification necessarily involved the use of several comparative skeletons of each genus in addition to constant reference to Olsen's (1960) standard work on the subject. However, after the analysis was underway it became apparent that, because of the nature of the archaeological specimens, we had to attempt to go further than Olsen had gone in his study; for instance, roughly 60% of the bovid bones from Fort Walsh were ribs and vertebrae, which were either not included or not given full treatment in Olsen's monograph. In addition, the smaller tarsals and all of the carpals were omitted from Olsen's work. The greater density and the resultant higher survivability rate of these small elements makes them an important component of many faunal assemblages.

Other difficulties, to which Olsen (1960) and Lawrence (1951) refer, centred on the fact that for many of the bones, no single character existed which allowed absolute separation of the two species. We realized that after at least two relatively intense North American comparative studies, there was little likelihood that any new absolutely separable characters would be found. Instead, we decided to take Olsen's characters (taken from Lawrence, other workers, and his own observations), add to them our own, and score each character of each element by checking its validity against as large a series of known comparative skeletons of each species as possible. In this way, we have been able to weight each character; in effect saying "character X of element Y proved useful in separating the two species in 18 of 20 cases, or 90% of the specimens examined". We hope that this will improve upon such vague qualifiers as "most of the specimens", "generally", "there is a tendency", etc.

Lawrence (1951:37) examined 10 *Bos* skeletons of several breeds as well as the skeletons of 12 *Bison*. Olsen (1960:6) included observations on an undesignated number of *Bos taurus*, representing 6 breeds, 18 *Bison bison* skeletons, and 9 skeletons of the zebu, *Bos indicus*. We have not examined or discussed the latter species in any way. Our own observations are based on 16 skeletons of *Bos taurus*, representing at least 5 breeds (Holstein, Ayrshire, Shorthorn, Longhorn, and Africander), and 27 skeletons of *Bison bison*, including individuals of both the *bison* and *athabascae* subspecies. The identification, location, and pertinent biological data of the specimens we examined are presented in Appendix 3.

A total of 192 characters have been described and rated; those marked with an asterisk were described by Olsen (1960). Olsen's inclusion of *Bos indicus* led us to paraphrase rather than directly quote his character descriptions; however, we have retained his terminology and tampered as little as possible with his wording. All of Olsen's characters have been included in this study, with the exception of his two characters for the thoracic vertebrae. Here Olsen has described characteristics specific to individual vertebrae (viz. the second thoracic and the eighth thoracic), whereas our approach has been to subdivide the thoracics into three regions and deal with characters that are more broadly applicable, in recognition of the difficulty in picking out individual thoracic vertebrae.

The simple illustrations were drawn by the authors using a Goodkin Indirect Drawing Viewer Model 5B, which, like a camera lucida, allows tracing of bone outlines and features. These drawings, coupled with the descriptions of the characters and <u>ready access to at least one adult specimen of each of the two species</u> should be clear enough to illustrate the distinguishing characteristics. Format of the plates follows the "field guide style", with the characters marked on the drawings and the appropriate character description on the facing page. Elements are described in the sequence of vertebral column and ribs, front limb, hind limb. In the case of paired elements, the left side is illustrated throughout.

Osteological terminology is a continuing problem in studies such as the present one, as there is no universally accepted set of standard terms for anatomical elements and orientation. Originally we had decided to follow von den Driesch (1976) for all directional nomenclature, but comments from some of our colleagues convinced us that using "cranial" and "caudal" can be confusing in some cases. While these two terms work well when referring to bones of the axial skeleton, their meaning is much less clear for limb elements. Rather than compound the confusion by using a dual terminology system for orientation (i.e. "anterior" and "posterior" for the appendicular skeleton, but "cranial" and "caudal" for the

axial skeleton), we decided to use the terms "anterior" and "posterior" throughout. Our application of these terms to limb elements is done under the assumption that the animal is in a standing position. For anatomical nomenclature we have followed that in Sisson and Grossman (1975).

Some characteristics were much more useful than others in distinguishing the two species. Immediately following the description of each character is a two-tiered table which provides a quantitative assessment of that character's reliability and usefulness. The upper tier gives the "success rate", a measure which, expressed as a percentage, indicates the number of cases in which the specimen exhibited the "correct" aspect of the character as described for that species. The success rates have been listed separately for each species; we found that often a character would have a high success rate for one species but not for the other, which limits its usefulness. The bottom tier is more detailed; it shows the number of specimens that agreed with a particular aspect of the character, the number that disagreed, and the number that fell into the "grey area" in between. In addition, this portion of the table gives a "preference factor" rating for each character, obtained through applying maximum likelihood theory. The preference factor provides a convenient shorthand way of expressing the probability that a given element, exhibiting a given character, belongs to *Bison* and, independently, the probability that it belongs to *Bos*. The application of maximum likelihood theory to this study is described in detail in Appendix 1.

Perhaps the most useful feature of this comparative study is its assessment of the utility of individual or grouped characters for the identification to species of a given element, rather than the list of characters *per se*. By scoring the "success" of each character on each reference specimen in our sample, and thus highlighting the most "reliable" characters, we hope to give the users of this guide a greater confidence in the results of their identifications. We also add a statistical approach which uses probability theory to evaluate the maximum likelihood that a given element under consideration is *Bos* or that it is *Bison*.

CAUTIONARY NOTES

1). We began with slightly over 200 characters, but winnowed out those that we found too vague to describe or score consistently. However, we retained all but two (as noted above) of the characteristics described by Olsen (1960), although several proved unreliable in our study. We have also retained several characters of our own that looked good early in the study but which ultimately proved too variable to be useful in distinguishing the two species.

Such characters can be quite misleading if only a few comparative specimens are checked, and we have included them here to demonstrate the difficulties inter-specific morphological variation presents to the comparative osteologist, and the value of large sample sizes. Because this study includes characters that proved useful and reliable, as well as those with low or ambiguous success rates, IT IS VITAL THAT NO CHARACTER BE CONSIDERED IN ISOLATION FROM ITS SUCCESS RATE AND/OR ITS PREFERENCE FACTOR RATING.

2). Please note that these characters apply only to distinguishing *Bos taurus* and *Bison bison*; we have not made any attempt to test the characters on other species within these genera.

Figure 12. Cervical 7, Anterior View

THORACIC VERTEBRAE

There are only a few characteristics to distinguish between the thoracic vertebrae of *Bos* and *Bison*. In both genera, there is a progressive reduction in the size of the transverse process from the anterior to the posterior thoracics; the neural spine becomes shorter from the fourth to the last thoracic; the posterior inclination of the neural spine increases from the first to the tenth thoracic; and the spine becomes narrower anteroposteriorly from the first to the twelfth thoracic vertebra.

It is helpful to separate the thoracics into three groups (anterior, mid, and posterior), based on the following distinctions:

Anterior Thoracics (T.1-T.4): see Fig. 13

- the neural spine is very long and wide anteroposteriorly;
- the transverse process is large, rounded and deep dorsoventrally;
- the posterior inclination of the neural spine is less than in the mid-thoracics;
- there is a distinct break between the anterior articular facets and the base of the neural spine.

Mid Thoracics (T.5-T.10): see Fig. 15

- the neural spine becomes progressively shorter as well as narrower anteroposteriorly;
- the transverse process becomes smaller, with the decrease in the dorsoventral depth especially noticeable;
- the neural spine has a pronounced posterior inclination;
- with the exception of the fifth thoracic, the anterior articular facets appear more continuous with the curve at the base of the neural spine.

Posterior Thoracics (T.11-T.13 or T.14): not illustrated

- the neural spine is short but the anteroposterior depth is greater than in the mid-thoracics;
- the posterior inclination of the neural spine decreases;
- the posterior articular processes are more prominent and complex;
- there is a distinct separation between the transverse process and the anterior articular process.

Fig. 94. Ventral View

(1)   In *Bison* the dorso-plantar depth of the medial condyle (A in Fig. 94) is
        measurably greater than that of the lateral condyle (B in Fig. 94). In *Bos* the two
        condyles are almost the same size, the medial being only slightly larger than the
        lateral.

        NOTE: It is necessary to use calipers to detect this distinction, as any size
        difference between the two condyles is not readily apparent to the eye alone. A
        more detailed discussion of this character, with the results of statistical testing of
        the sample means of the two species, is given in Appendix 2.

| success rate for *Bison* | 21/26 = 80.77% | | |

APPENDIX 1

A Preference Factor Approach to Distinguishing *Bos taurus* from *Bison bison*

General

There is considerable practical difficulty in distinguishing between partial skeletal remains of the two species, *Bos taurus* and *Bison bison*. Through observation of a series of known specimens, we have identified certain 'characters' which tend to differ between the two species. Associated with a character are two or more 'aspects' or 'classes' into which a specimen may fall. For example, a character might be 'the shape of the lateral condyle of the distal humerus'. The aspects might be 'concave', 'flat', and 'convex'.

The question naturally arises as to a quantitative means of expressing the value of a given character/aspect combination in differentiating between the two species and of combining the reults of observations of several characters. One approach, based on the statistical Maximum Likelihood concept, is discussed below.

Caution

Any specimen found is what it was (a denial of physical transmogrification). Statements such as "There is a 95% chance that this specimen is a *Bison*" are totally meaningless. The most that statistical reasoning can lead to is statements of the form: "If this specimen is a *Bos*, then the probability of encountering the observed character/aspect frequencies is considerably less than it would be if this were a *Bison*".

Assumptions

In order to use the maximum likelihood model, we had to make certain assumptions about the known specimens that we observed, as well as about a hypothetical archaeological specimen requiring identification. These assumptions are:

1). The *Bos* and *Bison* specimens we have used in deriving character/aspect frequencies are equivalent to a random selection from all *Bos*, or *Bison*, as applicable.

2). The archaeological specimen is equivalent to a random selection of one individual from its true species.

3). For a given character with n possible aspects, a *Bos* or *Bison* selected at random has probabilities

$$\{P_1, P_2, ..., P_n\} \quad \textit{Bison}$$

$$\{Q_1, Q_2, ..., Q_n\} \quad \textit{Bos}$$

of exhibiting each of the possible aspects. These P's and Q's are unknown and could be only approximately calculated from the examined specimens due to the small sample sizes involved. Indeed, the preference factors to be developed do not make any explicit assumption as to the values of the P's and Q's.

4). Characters are statistically independent for both *Bos* and *Bison*; that is to say that the observance of a particular aspect for character A yields no additional information as to the aspect for character B.

The Maximum Likelihood Concept

Suppose that the archaeological specimen is really from a *Bison* and, for simplicity, consider only one character with n possible aspects. Then a rather complicated expression

$$L_{Bison} (P_1, P_2, ..., P_n ; Q_1, Q_2, ..., Q_n)$$

can be written for the probability of occurrence of the observed frequencies in both the known specimens we scored and in the unknown specimen. Similarly, if it be assumed that the archaeological specimen is from a *Bos*, we can write a similar expression

$$L_{Bos} (P_1, P_2, ..., P_n ; Q_1, Q_2, ..., Q_n)$$

for the probability of occurrence of all results observed for this character.

If we knew the values of the P's and Q's, we could calculate L_{Bison} and L_{Bos} and express them as a ratio. If for example we found that:

$$L_{Bison} / L_{Bos} = 20$$

we could say that the observed results would be twenty times more likely if this were a *Bison* than if it were a *Bos*. It is not <u>really</u> correct to say "the specimen is 20 times more likely to be a *Bison* than a *Bos*", but this does provide a convenient verbal shorthand for expressing a more exact, albeit much wordier, statement.

Since we do not know the P's and Q's, we cannot calculate L_{Bison} and L_{Bos} directly. We can, however, calculate L_{Bison} and L_{Bos} where:

L_{Bison} = maximum value of L_{Bison} for all conceivable P's and Q's

with a similar definition for L_{Bos}.

The underlying assumption in the maximum likelihood is that the observed statistics are more likely to be likely than eccentric. If this assumption is true, then we should have $L_{Bison} \sim L_{Bison}$ and $L_{Bos} \sim L_{Bos}$.

If, on the contrary, the specimens we examined were very statistically biased for the character in question, or if the archaeological specimen were very atypical, there is just nothing statistics can do about it.

To spare the reader a considerable amount of algebra, a little calculus, and any further reference to the multinomial distribution, it turns out that, for a given character and aspect j (detected on the archaeological specimen)

$$R_j = L_{Bison} / L_{Bos} = N_j / D_j$$

where

$$N_j = ((B_j + 1)^{(Bj + 1)} \cdot B^B) / (B_j^{Bj} \cdot (B + 1)^{(B + 1)})$$

$$D_j = ((C_j + 1)^{(Cj + 1)} \cdot C^C) / (C_j^{Cj} \cdot (C + 1)^{(C + 1)})$$

and

B_j = number of *Bison* in our sample with aspect j

C_j = number of *Bos* in our sample with aspect j

B = number of *Bison* in our sample scored for the given character

C = number of *Bos* in our sample scored for the given character

Observations:

1). R_j depends on both the character and the aspect j of the archaeological specimen. One aspect of a character may convey little information whereas another might be of great help in differentiating *Bos* from *Bison*.

2). Very large $(>>1)$ or very small $(<<1)$ values of R_j indicate a good character/aspect combination for discrimination.

3). If our sample size were very large we would have:

$N_j = B_j / B$ and $D_j = C_j / C$ giving

$R_j = (B_j . C) / (C_j . B)$

but these are not true for small sample sizes.

4. If more than one of the documented characters is observed on the archaeological specimen, the preference factors multiply. Statistically, this is perfectly correct, but if wildly conflicting preference factors are found, a little skepticism is recommended.

APPENDIX 2.   METATARSAL CONDYLOID RATIOS

Antero-posterior depth measurements for medial and lateral condyles were determined for individual specimens, then expressed as a ratio and multiplied by 100% as follows:

depth of medial condyle x 100%
depth of lateral condyle

This is the percentage difference between the two condyles; for example, a value of 6.31 means that the medial condyle is 6.31% larger than the lateral condyle.

Although we observed differences in these ratios between the right and left metatarsals of the same individual, we felt that this was outweighed by differences between the two species; i.e. that the ratios fell into two distinct classes, one for the *Bos* specimens and another for *Bison*.

The Student t-test was used to test the significance of the difference between the *Bos* sample mean and the *Bison* sample mean. Measurements from the right metatarsal were used. The null hypothesis was that the two samples could have been drawn from the same population.

$$H_0: \mu_x - \mu_y = 0$$
$$H_1: \mu_x - \mu_y = 0$$

$$t = \frac{(\bar{x} - \bar{y}) - (\mu_x - \mu_y)}{\sqrt{\left(\frac{N_x s_x^2 + N_y s_y^2}{N_x + N_y - 2}\right)\left(\frac{1}{N_x} + \frac{1}{N_y}\right)}}$$

In our study

$N_x = 6$ $N_y = 17$
$\bar{x} = 1.795$ $\bar{y} = 5.4606$
$s_x^2 = 0.48211$ $s_y^2 = 1.50946$

$$ t = \frac{(1.795 - 5.4606) - 0}{\sqrt{\left[\dfrac{(6)(0.48211) + (17)(1.50946)}{6 + 17 - 2}\right]\left[\dfrac{1}{6} + \dfrac{1}{17}\right]}} $$

$t = -6.62005$

D.f. $= N_x + N_y - 2 = 21$

$P << 0.005$

Therefore, reject H_0 and conclude that there is a significant difference in the means of the ratios of the *Bos* sample and the *Bison* sample.

APPENDIX 4

CATALOGUE NUMBERS OF SPECIMENS USED IN ILLUSTRATIONS

Most of the illustrations were drawn using *Bos taurus* NMC 40163 and *Bison bison* NMC 75120. The exceptions are as follows:

Bos taurus Z-130 was used for Figs. 2, 11, 12, 38, 54, 55, 56, 57, 58, 59, 60, 66, 69, 72, 76, 77, 78, 79, 89, 90, 91, 92, 93

Bos taurus NMC 75122 was used for Figs. 23, 28, 30, 31, 32, 33, 47.

Bos taurus 75234 was used for Figs. 3, 39, 80, 81, and 82.

Bison bison NMC 75121 was used for Figs. 8, 14, 15, 28, 29, 30, 38, 39, 46, 52, 53, 65, 66, 67, 78, 94, 95, and 96.

Bison bison NMC 45416 was used for Figs. 2, 3, 9, 10, 11, 18, 19, 25, 26, 27, 34, 35, 36, 37, 74, 75, 85, 86, 87, and 88.

Bison bison AR 348 was used for Fig. 13.
